Key words: Caryophyllales, climatic occupancy, diversification rates, duplications, phylogenomics.

- The role played by whole genome duplication (WGD) in plant evolution is actively debated. WGDs have been associated with advantages such as superior colonization, various adaptations, and increased effective population size. However, the lack of a comprehensive mapping of WGDs within a major plant clade has led to uncertainty regarding the potential association of WGDs and higher diversification rates.
- Using seven chloroplast and nuclear ribosomal genes, we constructed a phylogeny of 5036 species of Caryophyllales, representing nearly half of the extant species. We phylogenetically mapped putative WGDs as identified from analyses on transcriptomic and genomic data and analyzed these in conjunction with shifts in climatic occupancy and lineage diversification rate.
- Thirteen putative WGDs and 27 diversification shifts could be mapped onto the phylogeny. Of these, four WGDs were concurrent with diversification shifts, with other diversification shifts occurring at more recent nodes than WGDs. Five WGDs were associated with shifts to colder climatic occupancy.
- While we find that many diversification shifts occur after WGDs, it is difficult to consider diversification and duplication to be tightly correlated. Our findings suggest that duplications may often occur along with shifts in either diversification rate, climatic occupancy, or rate of evolution.

Introduction

Understanding the causes and correlates of diversification within flowering plants has been a central goal of evolutionary biologists. Genomic and transcriptomic data have reinvigorated hypotheses associating whole genome duplication (WGD) with lineage diversification rate increases (e.g. Levin, 1983, 2002; Barker *et al.*, 2009, 2016; Estep *et al.*, 2014; Soltis *et al.*, 2014; Edger *et al.*, 2015; Puttick *et al.*, 2015; Tank *et al.*, 2015; Huang *et al.*, 2016; McKain *et al.*, 2016; Laurent *et al.*, 2017). It is not self-evident why WGDs would be associated with increases in lineage diversification. One hypothesis suggests that the additional genetic material provides a basis to generate new adaptations (Edger *et al.*, 2015), although this itself assumes a co-occurrence of adaptation and lineage proliferation (Levin, 1983). The apparent lack of precise co-occurrence of adaptation and lineage proliferation has been explained by the potential of a lag model (Schrantz *et al.*, 2012; Tank *et al.*, 2015) where diversification may follow WGD events. In the absence of overwhelming correlative signal, we are often unable to discern true ancient WGD events from aneuploidy without advanced genomic information such as synteny mapping (Dohm *et al.*, 2012). Because it is often difficult to distinguish the two, for simplicity we will define

WGD broadly to include putative ancient WGD events (paleopolyploidy) and ancient aneuploidy events. WGD events are thought to be a common occurrence and have been associated with an estimated 15% of angiosperm speciation events (Wood *et al.*, 2009). However, whether speciation by WGD is correlated with higher diversification rates remains highly debated (Mayrose *et al.*, 2011; Estep *et al.*, 2014; Soltis *et al.*, 2014; Tank *et al.*, 2015; Kellogg, 2016). Analyses based on recent WGD events have concluded that immediate extinction rates are higher for polyploid plants (Mayrose *et al.*, 2011; Arrigo & Barker, 2012). This may result from small initial population sizes and an increased dependence on selfing. Alternatively, despite the disadvantages of WGD, others have suggested that polyploids may be superior colonizers (Soltis & Soltis, 2000).

Indeed, extreme environments are associated with high amounts of WGD, with up to 87% of species restricted to areas that were glaciated during the last ice age consisting of polyploids (Brochmann *et al.*, 2004). However, in the example from Arctic plants, the high amount of WGD has occurred post-glaciation, representing a microevolutionary period, whereas previous studies often focus at much deeper macroevolutionary timescales (Mayrose *et al.*, 2011; Soltis *et al.*, 2014; Tank *et al.*, 2015). From the perspective of a short timescale, polyploidy has the

disadvantages of higher error rates in mitosis (Storchová *et al.*, 2006) and masking of deleterious mutations, allowing them to accumulate to higher frequencies in a population (Otto & Whitton, 2000). A suite of advantages may also arise, however, including gain of asexuality (Miller & Venable, 2000) and varying effects of heterosis (Comai, 2005). The net role played by these advantages and disadvantages on the macroevolutionary scale is difficult to determine from either the purely short-term or purely long-term timescales previously used.

The long-term consequence of WGD is a central question in macroevolution and comparative genomics. However, with a suite of advantages and disadvantages, much debate surrounds the importance and patterns of correlation of WGD (Comai, 2005). While polyploidization events can cause instant speciation, there is no reason to assume that these singular speciation events in themselves would influence large-scale diversification rate shifts when considering lineage survivorship. Instead, there may be other factors, such as the increase in genetic material, perhaps increasing genetic diversity or enabling adaptation, that cause long-term shifts in rates of diversification. Adaptations need not be associated with shifts in the tempo of diversification and those adaptations and shifts in diversification may not co-occur on the same branch (i.e. there may be a lag time; Donoghue, 2005; Smith *et al.*, 2011; Schranz *et al.*, 2012; Donoghue & Sanderson, 2015; Tank *et al.*, 2015; Dodsworth *et al.*, 2016). In the broader context of plant evolution, there are several possible outcomes of WGD in relation to the evolution and diversification of clades: no relationship between WGD and speciation rate or habitat shift/adaptation; WGD coincides with an increase of speciation rate, with or without a lag time; WGD promotes dispersal and habitat shifts, which has a mixed relationship with speciation rate; and a mixture (some association, some not), similar to the previous hypothesis but without explicitly promoting dispersal or habitat shift or speciation (e.g. adaptation could be more prominent than dispersal and habitat shift). Here, we contribute to this discussion on diversification and WGDs with an in-depth examination of the intersection of diversification and WGDs happening at a range of scales within the hyperdiverse Caryophyllales.

The Caryophyllales comprise *c.* 12 500 species in 39 families (Thulin *et al.*, 2016; APG IV: Chase *et al.*, 2016), representing *c.* 6% of extant angiosperm species diversity. The estimated crown age of Caryophyllales is *c.* 67–121 million yr ago (Ma; Bell *et al.*, 2010; Moore *et al.*, 2010). Species of the Caryophyllales exhibit extreme life-history diversity, ranging from tropical trees to temperate annual herbs, and from desert succulents (e.g. Cactaceae) to a diverse array of carnivorous plants (e.g. the sundews *Drosera* and pitcher plants *Nepenthes*). Such extraordinary diversity makes Caryophyllales a particularly useful system for investigating the relationship between WGD vs diversification and climate occupancy evolution. Our previous analyses using 62 transcriptomes representing 60 species across the Caryophyllales identified 13 well-supported ancient WGD events (Yang *et al.*, 2015). We have since nearly tripled the taxon sampling and assembled a dataset comprising high-coverage transcriptomes and genomes from 169 species across the Caryophyllales (Yang *et al.*, 2017), providing even greater power for resolving the number and phylogenetic

locations of WGD events. Moreover, the growth in the number of plant taxa on GenBank that are represented by traditional targeted sequences (e.g. *rbcL*, *matK*, ITS, etc.) and the growth of publicly available collections data (e.g. GBIF, iDigBio) provide excellent opportunities to apply phylogenetic and climate diversification approaches at fine scales in Caryophyllales.

By examining WGDs and diversification within the Caryophyllales, we present an important example. Not only does the dataset examined have a high density of transcriptomic sampling, the diversification of the bulk of Caryophyllales occurred during a time frame intermediate to that of most published studies that have probed a link between WGD and macroevolution. This time frame, between 10 and 100 Ma, is important for angiosperms, as much of the diversification that has led to the modern flora occurred during this period and most modern angiosperm families appeared by this time. Discussion of speciation rates, climate occupancy shifts, and WGDs would be flawed without accurate mappings of WGD events within this timescale. We compiled a dataset with extensive and precise mapping of WGD combined with a species-level phylogeny. The megaphylogeny approach has been used extensively in the past to combine data from many gene regions and across broad taxonomic groups to address evolutionary questions (Smith *et al.*, 2009). Here, we use this approach to help inform analyses from phylogenomic studies, and provide a broad context in which to examine these genomic phenomena. With half of the species sampled, this represents one of the largest and most exhaustive studies of WGDs, diversification rate, and adaptive shifts.

Materials and Methods

Sanger sequencing and assembly

A total of 248 new *matK* sequences were included in this study (Table 1). To generate these sequences, leaf samples were collected in silica in the field or from cultivated material, or were collected from herbarium sheets. DNA was isolated using either the Nucleon Phytopure kit (GE Healthcare Life Sciences, Pittsburgh, PA, USA), using the 0.1 g protocol and following the manufacturer's instructions, or the Doyle & Doyle (1987) protocol, with the addition of 1% PVP-40. An *c.* 950 bp region in the middle of the *matK* gene was amplified and sequenced using custom-designed primers (Table 2). PCRs were performed in 12.5 µl volumes with 0.5 µl of 5 mM primer for both primers, 5–20 ng of DNA template, 0.1 µl of GoTaq (Promega), 6.25 µl of Failsafe Premix B (Epicentre, Madison, WI, USA), and 4.7 µl of sterile, deionized water. Reactions were run on a Bio-Rad PTC 200 thermocycler (Bio-Rad) at Oberlin College. Individual PCRs were cleaned in 16.5 µl reactions containing 10 U of Exonuclease I (Affymetrix; ThermoFisher Scientific, Waltham, MA, USA), 2 U of shrimp alkaline phosphatase (Affymetrix), 8 µl of PCR product, and 8.5 µl of sterile, deionized water. Sanger sequencing of the resulting cleaned PCRs was conducted by Neogenomics (formerly SeqWright; Houston, TX, USA) using an ABI 3730xl automated sequencer (Applied Biosystems, ThermoFisher Scientific). The resulting forward and reverse sequences for each

reaction were trimmed and *de novo* assembled using default parameters of the Geneious assembler in Geneious versions 5–7 (Biomatters, Auckland, New Zealand).

Molecular data for phylogenetic reconstruction

Nucleotide data from the nuclear ribosomal internal transcribed spacers (ITS) and *phyC* gene, and the plastid loci *matK*, *ndhF*, *rbcL*, *trnH-psbA* spacer, and *trnL-trnF* spacer were used to

reconstruct the phylogeny. These data were gathered first using PHLAWD (Smith & Donoghue, 2008; Smith *et al.*, 2009) and then curated and combined with newly sequenced *matK* data for 124 additional species. This yielded the following sampling: ITS 2969 species, *matK* 2270 species, *ndhF* 417 species, *phyC* 172 species, *rbcL* 947 species, *trnH-psbA* 240 species, and *trnL-trnF* 1996 species. We used *matK*, *rbcL*, and *ndhF* sequences from *Aextoxicon*, *Apium*, *Berberidopsis*, *Campanula*, *Clethra*, *Coffea*, *Echinops*, *Helwingia*, *Ilex*, *Ipomoea*, *Lamium*, *Lonicera*, *Nyssa*,

Table 2 List of primers used to amplify the *matK* sequences newly reported here; within each primer name, the number indicates the approximate position of the primer in nucleotides downstream from the start of *matK*

Primer name	Sequence (5'→3')	Notes
matK.300F.Car	TTG CAG TCA TTG TGG AAA TTC C	Works broadly across most of Caryophyllales, but generally fails in Caryophyllaceae and Frankeniaceae
matK.1350R.Car	GCC AAA GTT CTA GCA CAA GAA AG	Works broadly across most of Caryophyllales
matK.210F.Car	TTC GGC TAA TGA TTC TCA CCA A	Designed specifically for Caryophyllaceae
matK.1345R.Car	GAG CCA AAG TTC TAG CAC AAG AA	Designed specifically for Caryophyllaceae
matK.1355R.Car	TGT GTT TAC GAG CTA AAG TTC TAG	Designed specifically for Caryophyllaceae
matK.300F.Fra	TCG CTG TCT TTG CTG AAA TTC C	Designed specifically for Frankeniaceae

Polysoma, *Primula*, *Santalum*, *Valeriana*, and *Viburnum* to represent outgroups.

Phylogenetic reconstruction

We conducted phylogenetic analyses with RAxML v.7.2.8 (Stamatakis, 2014) using the full analysis command, *-f a*, which conducts a rapid bootstrap and then a full maximum likelihood (ML) search. The combined bootstrap and ML search allows for a more thorough ML analysis where the initial rapid bootstrap results prime the ML analysis. However, we did not use the rapid bootstrap trees from this analysis and instead we conducted a full bootstrap, generating the bootstrap dataset using phyx (Brown *et al.*, 2017) and then conducting individual ML runs on each constructed bootstrap dataset. This allowed us to conduct the SH-like approximate likelihood ratio test (SH-aLRT; Guindon *et al.*, 2010) on the resulting bootstrap set. We conducted bootstraps within gene regions and we retained the individual bootstrap alignments to conduct additional analyses (i.e. bootstrapped alignments contained the same number of gene-specific sites as the empirical alignment). On each of the resulting trees of the bootstrap and the ML tree, we conducted SH-aLRTs as implemented in RAxML. These analyses calculate support for each edge while also finding the NNI-optimal topology. RAxML completed the likelihood search for each of these bootstrap replicates; however, the SH-aLRT analyses often resulted in an improved ML topology. The trees that resulted from the SH-aLRT, ML, and bootstrap samples, were used for further analyses. Because several deep relationships within Caryophyllales are hard to resolve without large amounts of molecular data that are unavailable for most of the taxa included in this analysis (Yang *et al.*, 2015), for all phylogenetic analyses we applied the following topological constraint: (Droseraceae, (*Microtea*, (Stegnospemataceae, Limeaceae, (Lophiocarpaceae, (Barbeuiaceae, Aizoaceae)))) as per previous analyses (Brockington *et al.*, 2009; Yang *et al.*, 2015).

Divergence time estimation

Few tractable options for divergence time estimation exist for datasets of the size presented here. We use the penalized likelihood approach (Sanderson, 2003) as implemented in the program TREEPL (Smith & O'Meara, 2012), which can handle large-scale phylogenies. The early fossil record of the Caryophyllales is

sparse with only a few known records (Arakaki *et al.*, 2011; Friis *et al.*, 2011): fossil pollen has been ascribed to Amaranthaceae (*Chenopodipollis*) from the Paleocene of Texas (Nichols & Trautman, 1971); a putative fossil infructescence from within the Phytolaccaceae in the Campanian has also been reported (Cevallos-Ferriz *et al.*, 2008), but this phylogenetic position has been disputed (S. Manchester, pers. comm.) and hence we excluded it; Jordan & Macphail (2003) describe a middle to late Eocene inflorescence from the species *Caryophylloflora paleogenica*, ascribed to Caryophyllaceae; pollen from Argentina within the Nyctaginaceae has been reported from the middle Eocene (Zetter *et al.*, 1999); and fossil pollen and seeds of *Aldrovanda* (Degreaf, 1997). The penalized likelihood method performs better when a calibration is used at the root. For this calibration, and because there is no fossil record for the earliest Caryophyllales, we use a secondary calibration from the comprehensive angiosperm divergence time analyses of Bell *et al.* (2010). We attached several other secondary calibrations to major clades where fossils are not available (Ocampo & Columbus, 2010; Arakaki *et al.*, 2011; Schuster *et al.*, 2013; Valente *et al.*, 2014; see Supporting Information Table S1 for detail on placement and calibrations). We conducted a priming analysis to determine the best optimization parameter values. We then performed a cross-validation analysis using the random cross-validation setting to determine the optimal smoothing parameter value.

Climate occupancy analyses

We downloaded 6592 700 georeferenced occurrences for the Caryophyllales from GBIF (accessed on 6 January 2015; <http://gbif.org>). After removing samples present in living collections, and therefore not necessarily representative of native climates, and removing samples whose localities were over water, 6009 552 samples remained. We extracted bioclimatic values for each coordinate using the 2.5 arcminute resolution data from WorldClim (<http://worldclim.org>). We only included taxa that had at least three samples in these analyses to reduce potential errors and to have the minimum number of samples required to calculate mean and variance. The resulting overlap of the taxa represented in both the geographic and genetic data was 2843 taxa. We conducted principal component analyses (PCA) on these extracted values. With both the bioclimatic values and the first two axes of the PCA, we conducted ancestral state reconstruction analyses.

We also compared ancestral states and Brownian motion rates of evolution between sister clades (comparing duplicated lineages with their sisters) for mean annual precipitation, mean annual temperature, and principal component axis 1. We calculated ancestral states for continuous characters using a single rate model and compared sister lineages. We also calculated and compared estimates of independent Brownian motion rates for sister lineages.

Diversification analyses

To map diversification rate shifts, we conducted MEDUSA (Alfaro *et al.*, 2009; Pennell *et al.*, 2014) analyses on the ML tree and the bootstrap trees. MEDUSA is far more computationally tractable than some other diversification estimation methods. Furthermore, we required the ability to feasibly integrate over the phylogenetic uncertainty within the phylogenetic dataset because of both the nature of the larger phylogenetic dataset and the inherent biological uncertainty within the Caryophyllales. MEDUSA fits a birth–death model of diversification (with parameters λ , net diversification (birth–death), and ϵ , relative extinction (death/birth)) before using stepwise Akaike information criterion (Burnham & Anderson, 2002) to identify shifts in rates of diversification. These complementary analyses accommodate topological and branch length uncertainty. We employed a birth–death model for 97 chronograms generated from nonparametric bootstrapping of the original matrix, inferring ML trees in RAXML, and estimating divergence times in treePL using the temporal constraints described earlier. We discarded three trees based on poor fossil placement resulting from phylogenetic uncertainty causing fossil placements to conflict.

Whole genome duplication identification

To identify WGDs (procedure described later), we generated a tree based on transcriptomic data. For this tree, we used 178 ingroup datasets (175 transcriptomes, three genomes) representing 169 species in 27 families and 40 outgroup genomes (Tables S1, S2 in Yang *et al.*, 2017). We mapped putative WGD events using multiple strategies: gene tree topology, plotting synonymous distance, and chromosome counts (Yang *et al.*, 2015, 2017). For gene tree topology analyses, we performed two alternative strategies for mapping duplication events from gene trees to the species tree: mapping to the most recent common ancestor (MRCA), or mapping to the species tree only when gene tree and species tree topologies are compatible.

To conduct synonymous distance analyses, we performed the following procedure. For all ingroup Caryophyllales transcriptome datasets, we calculated the distribution of paralog synonymous distance following the same procedure as Yang *et al.* (2015). We reduced highly similar peptide sequences with CD-HIT (-c 0.99 -n 5) (Li & Godzik, 2006). We also carried out an all-by-all BLASTP within each taxon using an E-value cutoff of 10 and -max_target_seq set to 20. Resulting hits with pident < 20% or niden < 50 amino acids were removed. We removed sequences

with 10 or more hits to avoid overrepresentation of gene families that experienced multiple recent duplications. We used the remaining paralog pairs and their corresponding coding sequence to calculate synonymous substitution rate (K_s) values using the pipeline https://github.com/tanghaibao/bio-pipeline/tree/master/synonymous_calculation (accessed 29 November 2014). The pipeline first carries out pairwise protein alignment using default parameters in CLUSTALW (Larkin *et al.*, 2007), back-translates the alignment to a codon alignment using PAL2NAL (Suyama *et al.*, 2006), and calculates the K_s using yn00 as part of the PAML package (Yang, 2007), with Nei–Gojobori correction for multiple substitutions (Nei & Gojobori, 1986). We obtained chromosome counts from the Chromosome Counts Database (CCDB; <http://ccdb.tau.ac.il> accessed 5 October 2015). When multiple counts were reported from different authors or different plants, we erred on the conservative estimate and recorded the lowest number. For species that were not available in the database, we found counts from the literature (e.g. Jepson eFlora <http://ucjeps.berkeley.edu/eflora/> and Flora of North America <http://floranorthamerica.org>) or by a consensus from species of the same genera.

Results and discussion

Phylogenetic results

Phylogenetic analyses showed strong support based on bootstrap and SH-aLRT values for the monophyly of most Caryophyllales families (see Fig. S1). We found strong support for the carnivorous clade, including Droseraceae, Ancistrocladaceae, Nepenthaceae, Drosophyllaceae, and Dioncophyllaceae. There was also strong support for this clade as sister to a clade including Frankeniaceae, Tamaricaceae, Plumbaginaceae, and Polygonaceae. However, relationships among the families showed more varied support. There was weak support for the placement of other families relative to other early diverging Caryophyllales (see Fig. S1). There was strong support for Caryophyllaceae as sister to Amaranthaceae. There was very weak support for Aizoaceae as sister to Phytolaccaceae + Nyctaginaceae. As with previously published analyses, there was no support for the monophyly of Phytolaccaceae in the traditional sense (i.e. including Phytolaccaceae *sensu stricto*, Petiveriaceae, and *Agdestis*, APG IV) and very weak support for the placement of Sarcobataceae. There was also weak support for the relationships among Limeaceae, Molluginaceae, and the Portulacineae. Many of these relationships have been found to be strongly supported but conflicting in different analyses (Brockington *et al.*, 2009; Soltis *et al.*, 2011; Smith *et al.*, 2015; Yang *et al.*, 2015; Walker *et al.*, 2017). Here, we focused less on the systematic resolution within the Caryophyllales and instead examined the potential relationship of diversification and climate occupancy shifts to WGDs. Therefore, we placed more emphasis on including more taxa over that of more gene regions (i.e. transcriptomes) at the cost of more missing data. Confident resolution of many of the systematic relationships will require genomic and transcriptomic sampling, as well as more thorough taxon sampling (Yang *et al.*, 2017).

Climate occupancy reconstruction results

We performed climate occupancy ancestral reconstruction analyses on the phylogeny of 2843 taxa that included taxa with at least three sampled geographic coordinates (Figs 1–3). We conducted these analyses for visualization and for comparison with diversification and WGD results (see later). Results for individual bioclimatic variables and principal components can be found in Figs S2–S4. Bioclimatic variable 1 (mean annual temperature, Fig. 1) showed that there are several strong phylogenetic patterns of clades with preferences for colder or warmer regions. For example, Polygonaceae, Caryophyllaceae, and Montiaceae each are dominated by taxa with preferences for cold environments, although each also contains early-diverging taxa with preferences for warm environments. By contrast, taxa inhabiting warm environments predominate in Cactaceae, Amaranthaceae, Aizoaceae, the carnivorous clade (Droseraceae, Drosophyllaceae, Nepenthaceae, Ancistrocladaceae, Dioncophyllaceae), and the phytolaccoid clade (Nyctaginaceae, Phytolaccaceae, Petiveriaceae, Sarcobataceae, and *Agdestis*). Bioclimatic

variable 12 (mean annual precipitation) showed a comparatively consistent pattern of relatively dry to intermediately wet clades throughout the group. Indeed, only a few clades inhabiting wet ecosystems (in this case, the wet tropics) exist in the Caryophyllales, specifically small groups within the carnivorous clade, the phytolaccoids, early-diverging Polygonaceae, and other small groups throughout the Caryophyllales. The principal component loadings are presented in Figs 2 and S5. Principal component 1 (PCA1) showed significant differentiation throughout the Caryophyllales, as, for example, early-diverging Polygonaceae vs the rest of Polygonaceae, early diverging Caryophyllaceae vs the rest of Caryophyllaceae, phytolaccoids vs Aizoaceae, and Portulacineae + relatives vs Cactaceae, to name a few. These results generally reflect the extensive ecological diversification throughout the group. They also reflect significant diversification in the temperate regions of the world, especially within the Caryophyllaceae and Polygonaceae, contrasted with extensive diversification in the succulent lineages (especially Aizoaceae and Cactaceae) found in relatively dry and warm environments.

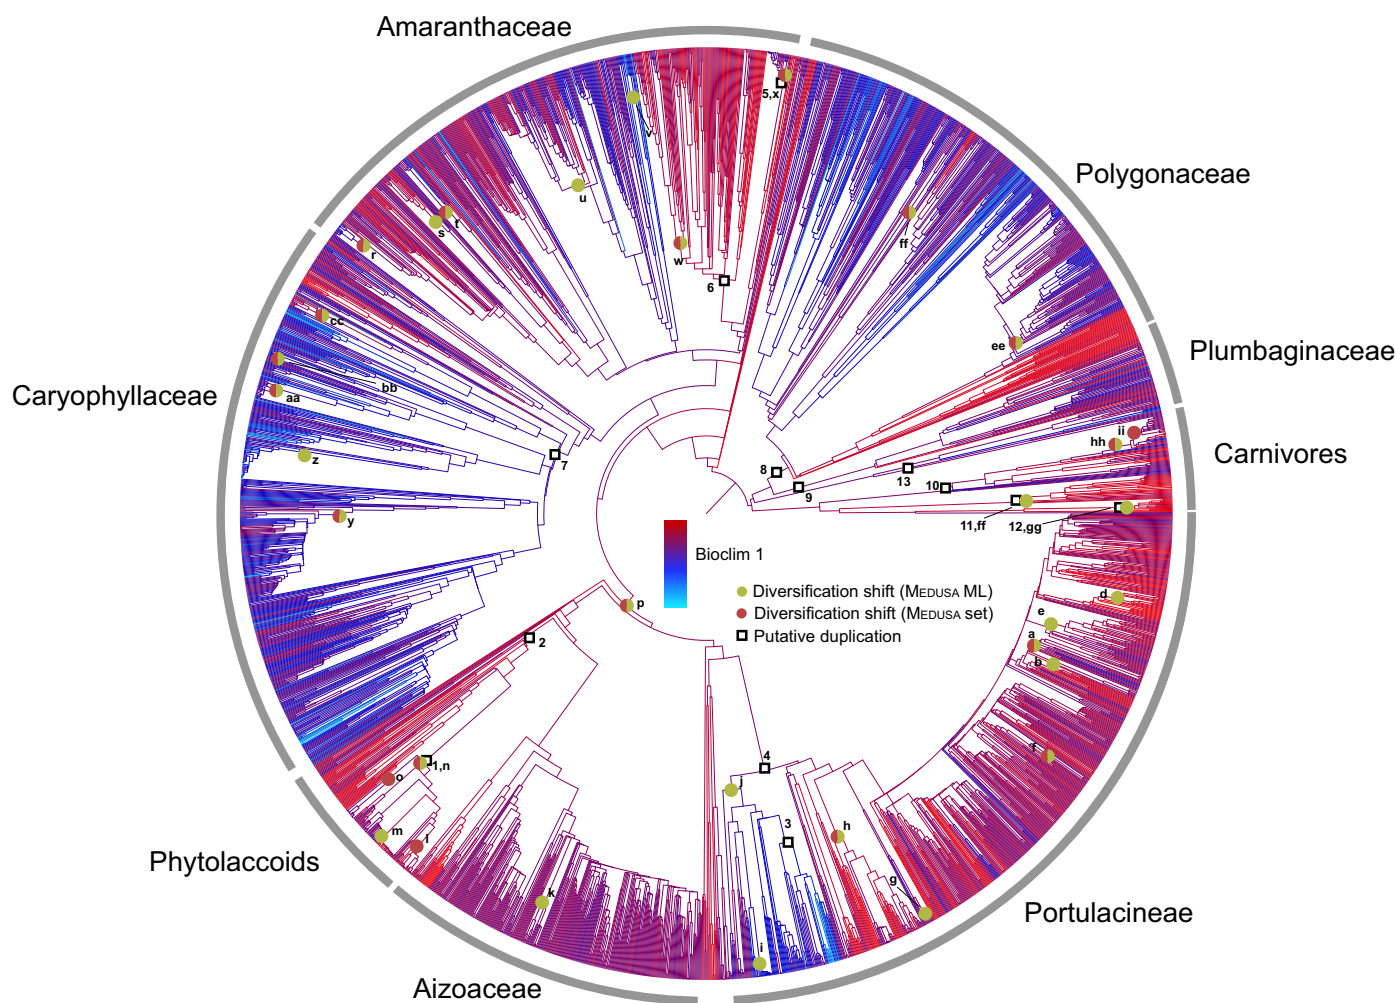

Fig. 1 Chronogram of the Caryophyllales with putative whole genome duplications mapped along with identified diversification shifts. Diversification analyses were performed on the maximum likelihood tree as well as the bootstrap tree set and those shifts that were identified in both groups are shown. The branches are colored based on Bioclim variable 1 (mean annual temperature). The numbers next to duplications correspond to the numbers in Table 3 and the letters next to diversification shifts correspond to Table 4.

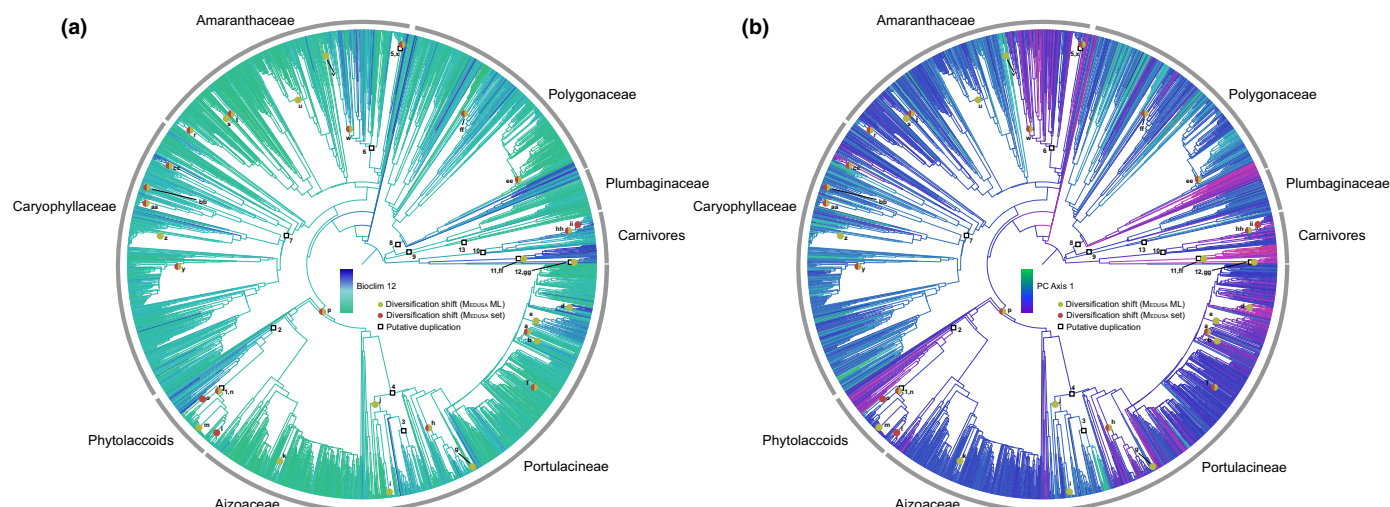

Fig. 2 The chronograms and mapping of diversification and whole genome duplications are as in Fig. 1 (see key for details). The branches in (a) are colored based on Bioclim variable 12 (mean annual precipitation), and those in (b) are based on the principal component analyses (PCA) axis 1.

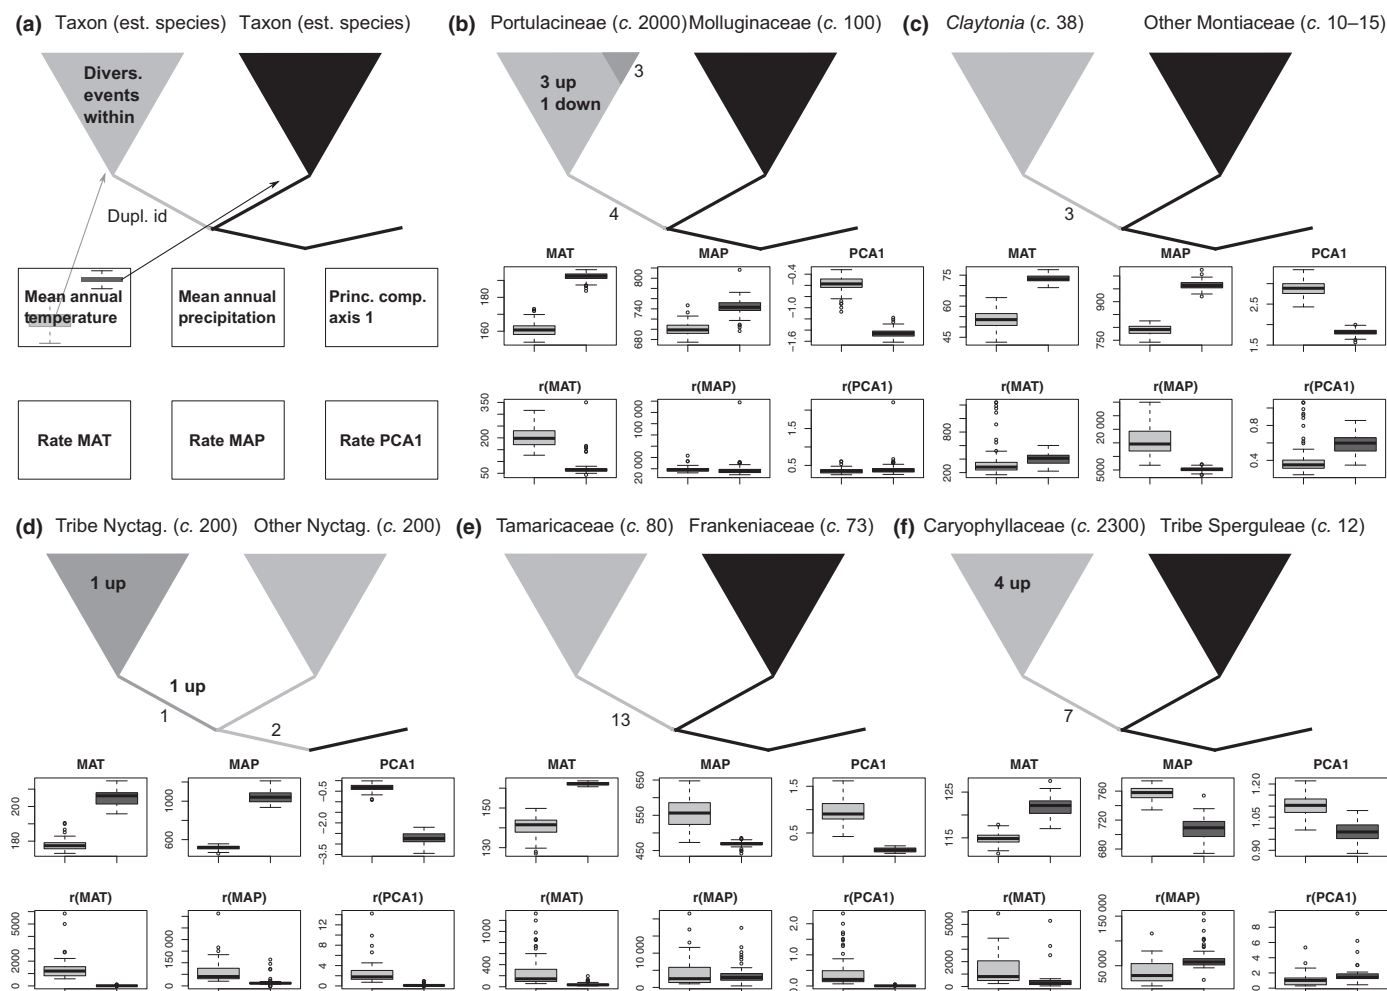

Fig. 3 Summary of whole genome duplication (WGD) events (with numbers corresponding to those in Table 3), distributions for climatic variables calculated between left and right clades (MAT, mean annual temperature; MAP, mean annual precipitation; PCA1, principal component axis 1), distributions for the rate of climatic variables calculated between left and right clades, and diversification shifts. Numbers along branches denote WGDs, with the numbers corresponding to those in Fig. 1 and Table 3. Numbers inside clades denote the number of diversification rate shifts. Estimated (est.) species numbers are listed beside clade names. Box plots show the values estimated (ancestral values are listed in the top rows, rates in the bottom rows) for both the left and right clades across bootstrap samples. Clades shaded grey denote a WGD; (b–d) have nested WGDs.

Table 3 Summary of whole genome duplication (WGD) events at identified clades with distance to diversification shift in the maximum likelihood (ML) and bootstrap (BS) tree sets and climate occupancy information

No.	Putative WGD	Distance to diversification shift in nodes ML (BS)	Subtending species (sister)	Mean annual temperature (°C) (sister)	Mean annual precipitation (mm) (sister)
1	Tribe Nyctagineae within the Nyctaginaceae	0 (0)	123 (40)	17.49 (20.08)	482.9 (997.08)
2	Phytolaccoid clade	6 (6)	182 (407)	19.64 (18.36)	1007.58 (452.47)
3	<i>Claytonia</i>	na	38 (15)	5.28 (7.25)	790.5 (970.36)
4	Portulacineae	1 (1)	1600 (38)	16.19 (19.35)	699.87 (736.42)
5	<i>Amaranthus</i>	0 (0)	28 (1)	16.27 (27.09)	797.74 (117.63)
6	Tribe Gomphrenoideae within Amaranthaceae	7 (7)	172 (41)	17.91 (16.65)	871.95 (1289.5)
7	in Caryophyllaceae (Alsinoideae+Caryophylloideae sensu Greenberg and Donoghue 2011)	9 (9)	793 (13)	11.44 (12.06)	761.43 (720.00)
8	Polygonaceae	13 (13)	670 (70)	16.3 (16.89)	1084.17 (794.28)
9	Plumbaginaceae	na	70 (670)	16.89 (16.3)	794.28 (1084.17)
10	Droseraceae	8 (na)	67 (108)	16.3 (19.08)	1280.57 (1491.72)
11	Nepenthaceae	4 (na)	89 (19)	22.52 (20.05)	2170.5 (1611.63)
12	Ancistrocladaceae	0 (na)	15 (3)	24.17 (25.6)	1899.13 (2882.4)
13	Tamaricaceae	na	19 (3)	14.09 (16.21)	568.32 (469.61)

Numbers correspond to those in Figs 1 and 2. Entries with 'na' suggest no significant shift near node.

Diversification

Significant shifts in diversification were detected in most major clades (Table 4; Fig. 1). The results from diversification analyses on the ML tree and bootstrap tree set were generally congruent with each other. However, there were discrepancies (Fig. 1). The bootstrap set recovered many shifts in Polygonaceae, the carnivorous clade, Caryophyllaceae, some shifts within Cactaceae, phytolaccoids, and Amaranthaceae. Disagreements over the existence and placement of shifts are primarily within Portulacineae, Aizoaceae, and Amaranthaceae. Overall, MEDUSA detected 27 increases in diversification rate using the ML tree and 16 increases using the bootstrap trees. Given the relative lack of support of some of the branches in the phylogeny, we find the MEDUSA results on the set of bootstrapped trees to be the most conservative, whereas the ML results are suggestive but not definitive of diversification shifts.

Duplications, diversification, and climate occupancy

Whole genome duplication analyses showed 13 putative WGDs that could be mapped to clades (i.e. involve more than one taxon in the dataset; Table 3; Figs 1–3). Many of these were found in early diverging lineages as opposed to nested deep within families, although there are WGDs identified in *Amaranthus* and *Claytonia*. We also found evidence of nested WGDs within the phytolaccoids and Portulacineae. In addition to these deeper WGDs, there were several more recent WGDs that were present in K_s plots but could not be mapped to a clade (Yang *et al.*, 2017). By sampling more extensively, Yang *et al.* (2017) and Walker *et al.* (2017) found additional WGD events within the Caryophyllales. We will surely find additional WGDs events in other lineages as more effort is placed on denser taxon sampling using genomes and transcriptomes. We did not explore WGDs that could only be mapped to terminal branches as we could not verify these phylogenetically. Further discussion of specific results related to the WGDs themselves can be found in Yang *et al.* (2017) and Walker *et al.* (2017).

To better examine whether WGDs coincide with diversification rate shifts, increases and decreases, or notable changes in climate tolerance, we mapped WGDs onto the large phylogenies and summarized the number of species and climate occupancy information for each clade (Tables 3, 4; Figs 1–3). Some WGD events were associated with synchronous diversification events. For example, within Nyctaginaceae, a WGD event occurs on the same branch (leading to Tribe Nyctagineae; Douglas & Spellenberg, 2010) as an increase in diversification rate in both the ML tree and the bootstrapped dataset (Fig. 1, dup: 1 div: n). These events were also associated with a shift in life history and occupancy from an ancestral woody habit in the tropics to the largely herbaceous, arid-adapted temperate Nyctagineae. This was also the case for *Amaranthus* (Fig. 1, dup: 5 div: x). Other coincident diversification and WGD events in the Droseraceae and Nepenthaceae were only supported by the ML tree. Although these correlated events may, in fact, be accurate, we will reserve

more comments for when these are more confidently resolved. Other than these simultaneous shifts and one diversification shift at the base of the MRCA of Nyctaginaceae + Cactaceae, all other shifts in diversification occurred more recently than WGD events. Several authors have suggested that this lagging pattern may be common at the broader angiosperm scale (Schranz *et al.*, 2012; Tank *et al.*, 2015), although the expected distance of the diversification shift from the WGD event was not specified (this is discussed more later on). In the results presented here, some diversification events occur shortly after the WGD event, such as within the Amaranthaceae (dup: 6) and Portulacineae (dup: 4). For others, it is difficult to determine whether the diversification events that occur after the WGD events are significantly close to the WGD to warrant suggestion of an association (e.g. dup: 7, dup: 10, dup: 8). More description of a model that would generate a null expectation would be necessary to determine what is 'close enough' (see discussion later).

Many of the other inferred lineage diversification rate shifts were associated with very recent, rapid radiations within genera such as those documented within *Commicarpus* (Nyctaginaceae), *Dianthus* (Caryophyllaceae), *Cerastium* (Caryophyllaceae), *Arenaria* (Caryophyllaceae), and *Salicornia* (Amaranthaceae), to name a few (Table 4). Although polyploids were reported in these clades, we were unable to pinpoint the phylogenetic location of any WGD with our current taxon sampling (e.g. *Dianthus*; Carolin, 1954; Weiss *et al.*, 2002). Increased sampling of transcriptomes and genomes will shed more light in these areas. While we only find a few WGDs that coincide well with diversification rate shifts, it is important to note that the uncertainty in the phylogenies makes it difficult to map anything but the strongest diversification signals. This discrepancy can be seen in the difference between the number of events supported by the ML analyses and those supported by the bootstrap analyses. It is possible that additional sequence data will improve phylogenetic resolution and confidence, and that, consequently, additional diversification events will emerge.

Equally interesting to the few WGD events associated directly with diversification are the WGD events associated with general shifts in climate tolerance. WGDs in the Polygonaceae, Caryophyllaceae, Montiaceae, and the Tribe Nyctagineae appear to be associated with movement into colder environments (Figs 1, 2, S2, S3). Species arising after the WGD within the Amaranthaceae occupy wetter environments than the sister clade. The WGDs within the carnivorous plants were also associated with shifts in environment as Nepenthaceae are found in very wet environments and the Droseraceae are found in somewhat drier environments, at least comparatively. However, in these cases, perhaps the development of the wide array of morphologies associated with carnivory, apart from *Drosophyllum*, is more obviously associated with the WGD (Walker *et al.*, 2017).

While these qualitative assessments suggest potential correlations of shift in the climate occupied and WGDs, more specific and direct comparisons are necessary to quantify the extent of the shifts. For many of the clades experiencing WGD, a direct comparison with a sister clade is difficult because the sister may consist of a single species, another clade with WGD, or another

complication. For example, there are WGDs at the base of both Polygonaceae and Plumbaginaceae as well as Nepenthaceae and Droseraceae. However, we made a direct comparison of five duplicated lineages (see Fig. 3) in both values (i.e. ancestral states between sister clades) and variances (rate of Brownian motion) of climatic variables. In each case, the duplicated lineage occupied a colder mean annual temperature. This was also the case with the nested WGDs of Portulacineae and the Tribe Nyctagineae.

Of course, we do not suggest that all WGDs are associated with a shift to a colder climate. While such a pattern may exist in some clades (e.g. Caryophyllaceae), we emphasize that we observed a shift in the climate occupied rather than the direction of the shift. This, too, may only be the case with the examples shown here. Mean annual precipitation did not exhibit a clear pattern with some clades occupying a higher precipitation and some occupying lower precipitation. Perhaps the best summary of climatic occupancy is the principal components of all the climatic variables. Here, while the shift in units is less easily interpreted, duplicated clades occupied different climatic spaces than did sister lineages. This supports the hypothesis that WGD events are associated with adaptations. Here, many of these adaptations are associated with shifts in climatic occupancy. This necessitates further examination within the Caryophyllales as more data are gathered. This also suggests further examination with other angiosperm clades in order to investigate how general these results are.

The rates of climate occupancy evolution show more complicated patterns. While some clades, such as the Portulacineae, showed significant increase in a rate of climate occupancy evolution as compared with the sister clade (e.g. MAT), no clear pattern emerged across all comparisons. There were other shifts in rate such as with MAT and MAP in the Nyctagineae and Montiaceae, but these were not as strong as the pattern of climate occupancy itself discussed earlier.

We suggest caution with any overinterpretation of the results presented here. With each of the patterns presented, it is important to consider them in the context of uncertainty, both inherent in the biological processes that generate the phylogeny and in the analyses associated with large-scale datasets. Large phylogenies and datasets allow for broad examinations, but uncertainty makes precise mapping of weaker signals difficult. Furthermore, large datasets often have poor overlap because of a lack of data availability, and many of these clades require genomic datasets for accurate resolution (e.g. Arakaki *et al.*, 2011; Yang *et al.*, 2015; Walker *et al.*, 2017). The comparisons of sister clades for climatic occupancy analyses and diversification analyses assume accurate identification of relationships that may differ between datasets. Additionally, large geographic datasets often contain extensive uncertainty and data cleanliness challenges because of the enormous size of the datasets. Furthermore, the biological reality of nested WGDs complicates analyses and interpretations. Focused studies with increased taxon sampling will contribute greatly to our understanding of the patterns presented (as suggested by Edwards *et al.*, 2015). Increasing taxon sampling may help, but additional sequence data and specimen data for phylogenetic analyses, WGD mapping analyses, and climate occupancy

characterization will improve our precision in these investigations. Hence, the results presented here will, we hope, contribute to a growing discussion but they will surely not be the last word.

What emerges from these analyses of WGD, diversification, and climate occupancy? It would appear that, perhaps not unexpectedly, the patterns are complex and mixed. Some WGDs are associated directly with diversification events, some are associated with shifts in climate tolerance, others are coincident with shifts in rates of climate occupancy evolution, and still others are associated with known adaptations (carnivory, habit shifts associated with montane habitats, etc.). Some diversification shifts follow WGD events. However, it is unclear whether these events are linked or correlated and, if so, if they are correlated more with diversification than an additional adaptation or other evolutionary pattern or process. As data increase in these groups and as confidence increases in the phylogenetic relationships as well as the placement of both diversification and WGD events, we will be able to better address these questions. However, at least for the Caryophyllales, it does not appear as though diversification is tightly linked with WGD. Instead, for the clades that can be tested, we find shifts in climate occupancy correspond well to WGD.

Suggestions for moving forward

Whole genome duplications are almost certainly among the dominant processes that contribute to major evolutionary events within plant lineages. This may be in the form of increased diversification, development of novel traits, adaptation to new environments, and many other events (e.g. Schubert & Vu, 2016; Clavijo *et al.*, 2017). However, for several reasons, these events (i.e. WGDs and other evolutionary events) may not occur simultaneously. In fact, there may be little to no expectation that the events will occur simultaneously (e.g. Donoghue, 2005; Schranz *et al.*, 2012; Donoghue & Sanderson, 2015; Tank *et al.*, 2015; Dodsworth *et al.*, 2016). In any case, more precise expectations and null models need to be developed to allow for reasonable tests of the correlations among these events. For example, there may be shifts in diversification that follow a WGD, but is it close enough, or frequent enough, to infer that the two events are related? Is correlation possible or identifiable if, as is expected, intervening lineages have become extinct? These questions would benefit from simulation studies where the true correlation pattern is known. Furthermore, more precise connections should be made to the biology of speciation and genome WGDs to better determine why, specifically, WGDs would be expected to correspond with any diversification pattern instead of adaptations, which may or may not correspond with increases or decreases in speciation. While still challenging, investigating the fate of and patterns of selection within individual genes (e.g. subfunctionalization and neofunctionalization) may shed light on the genomic basis of post-WGD and possibly allow for more concrete expectations for diversification. With the availability of genomes and transcriptomes, this is now beginning to become a possibility (e.g. Brockington *et al.*, 2015; Walker *et al.*, 2017). Only when these suggestions are linked to more specific biological hypotheses

will we be able to better understand the ultimate impact of WGD in plant evolution.

Acknowledgements

We thank Caroline Parins-Fukuchi for discussion of the project and comments on the manuscript. We thank Gregory Stull, Oscar Vargas, Ning Wang, Sonia Ahluwalia, Jordan Shore, Lijun Zhao, Alex Taylorm, and Drew Larson for helpful comments on the manuscript. The authors thank Hilda Flores, Helga Ochoterena, Tom Wendt and the staff at the Plant Resources Center at the University of Texas at Austin, the Lyon Arboretum, David Anderson, John Brittnacher, Anna Brunner, Joseph Charboneau, Arianna Goodman, Heather-Rose Kates, Patricia Hernández Ledesma, Lucas Majure, Nidia Mendoza, Michael Powell, Rick Ree, Carl Rothfels, Flora Samis, Jeffrey Sanders, Elizabeth Saunders, Rich Spellenberg, Greg Stull, Mats Thulin, Erin Tripp, and Sophia Weinmann for help with obtaining material. We thank the Cambridge University Botanic Gardens for growing material for this study. This work was supported by NSF DEB awards 1352907 and 1354048.

Author contributions

S.A.S., J.F.W., Y.Y., M.J.M., and S.F.B. designed the research. C.P.D., R.B., N.L., and N.A.D. collected data. S.A.S., J.W.B., and Y.Y. analyzed the data. S.A.S. led the writing. All authors read and contributed to the manuscript.

About *New Phytologist*

- *New Phytologist* is an electronic (online-only) journal owned by the New Phytologist Trust, a **not-for-profit organization** dedicated to the promotion of plant science, facilitating projects from symposia to free access for our Tansley reviews.
- Regular papers, Letters, Research reviews, Rapid reports and both Modelling/Theory and Methods papers are encouraged. We are committed to rapid processing, from online submission through to publication 'as ready' via *Early View* – our average time to decision is <26 days. There are **no page or colour charges** and a PDF version will be provided for each article.
- The journal is available online at Wiley Online Library. Visit **www.newphytologist.com** to search the articles and register for table of contents email alerts.
- If you have any questions, do get in touch with Central Office (np-centraloffice@lancaster.ac.uk) or, if it is more convenient, our USA Office (np-usaoffice@lancaster.ac.uk)
- For submission instructions, subscription and all the latest information visit **www.newphytologist.com**
